INTRODUCTION
Medulloblastoma is a primitive neuro-ectodermal tumor. It is common in childhood, but rarely seen at adult age, comprising only 1% of primary brain tumors.[1] There are not many studies concerning the treatment of these tumors. Medulloblastomas most commonly present with signs of increased intracranial pressure, including nocturnal or morning headaches, nausea, vomiting, and altered mental status. Treatment involves maximal surgical resection, craniospinal irradiation, and chemotherapy. Approximately 70% of the patients have a long-term survival rate but usually at the cost of significant neurocognitive impairment.[2]

CASE REPORT
A 31-year-old man presented to the emergency department (ED) with a chief complaint of nausea and vomiting for one week duration. He reported being homeless and eating out of the garbage for nutrition. The patient also stated several episodes of non-bloody, non-bilious emesis not associated with abdominal pain. The remainder of his review of symptoms was grossly unremarkable. Initial ED vital signs were: blood pressure 135/87 mmHg, pulse 53 beats per minute, oral temperature 97 degrees Fahrenheit, respiratory rate 20 breaths per minute, and pulse oximetry 99 percent on room air. Physical exam demonstrated a disheveled but pleasant young man in no apparent distress with dry mucus membranes. Additionally, he had clear breath sounds, a slow, regular heart rate without murmurs, rubs or gallops, a soft, non-tender, non-distended abdomen, and no gross focal neurologic deficits. The patient was treated for a presumed case of food poisoning with ondansetron, intravenous fluids and discharged.

Later that same evening, the patient returned to the emergency room with a new chief complaint of dizziness and difficulty ambulating. His vital signs were as follows: blood pressure 135/87 mmHg, pulse 53 beats per minute, oral temperature 97 degrees Fahrenheit, respiratory rate 20 breaths per minute, and pulse oximetry 99 percent on room air. The patient...
showed nauseous and ill appearance. Repeat neurological exam demonstrated impressive dysmetria, a positive Romberg sign, and most significantly, a wide, unsteady, slowed gait. ED non-contrast computed tomography of the brain demonstrated a 5.1 cm left cerebellopontine angle mass with significant obstructive hydrocephalus and bilateral cerebellar tonsillar herniation (Figures 1–3). Neurosurgery was emergently consulted and treatment was recommended with IV dexamethasone and furosemide. Repeat vital signs showed a blood pressure of 180/100 mmHg, a pulse 39 beats per minute and a respiratory rate of 10 shallow breaths per minute. Due to the patient's rapid clinical decompensation, the patient was taken for an emergent ventriculostomy and left posterior fossa craniectomy for subtotal resection of the mass. Immediate frozen section revealed a grade IV medulloblastoma. During the hospital course, the patient was given craniospinal irradiation with chemotherapy, and was eventually discharged from the hospital to an assisted living facility after an uneventful 15-day course with the aid of social work.

DISCUSSION

Medulloblastoma is the most common malignant brain tumor of childhood (among children aged less than 19 years), accounting for approximately 20% of all primary tumors of the central nervous system.\(^1\) The incidence peaks at 5–9 years of age and approximately 70% of the patients are diagnosed before the age of 20 years. Interestingly, there is a slight increase in the incidence between 20–24 years of age, and the tumor is extremely rare after the fourth decade. Furthermore, medulloblastoma accounts for only 1% of all primary brain tumors in adults, a finding which may be attributed to the embryonal origin of the tumor.\(^1\) Anatomically, these tumors classically arise in the cerebellar midline in children and more laterally in the cerebellar hemispheres in adults.\(^3\) Medulloblastoma clinically presents with signs of increased intracranial pressure, secondary to mass effect blocking drainage through the 4th ventricle. Signs of increased intracranial pressure are usually present 1 to 5 months prior to diagnosis.\(^4\) The initial symptoms can include repeated episodes of vomiting or morning headache, but can develop ataxia, stumbling gait and frequent falls. Head titubation (or head bobbing), nystagmus, facial sensory loss, and diplopia secondary to sixth cranial nerve palsy may also be present.\(^4\) Treatment involves gross neurosurgical resection and may additionally include craniospinal irradiation with adjuvant chemotherapy with agents such as cisplatin, lomustine, cyclophosphamide, and vincristine.\(^2\) The majority of patients have a favorable 5-year survival, but with significant neurocognitive impairment and sequelae.\(^5\)

There are three clinically interesting findings in this case. First, medulloblastoma diagnosed in an adult is a rare occurrence. Second, it is rare for a patient to escape the surgical and postsurgical management of a
medulloblastoma without any serious neurocognitive impairment. Third, this patient exhibited Cushing’s triad, a rare clinical finding. The Cushing response, or "reflex", as first described by Dr. Harvey Cushing in the early 1900s manifests as a result of an abrupt increase in intracranial pressure.\(^6\) It consists of the classical triad of hypertension, bradycardia, and slow, irregular breathing elicited by the stimulation of mechanically sensitive regions in the paramedian caudal medulla. The proximate cause of the Cushing response is an anatomical distortion of the lower brain stem. This can be either from a mass in the posterior fossa, or more often, from a large mass in one of the hemispheres causing a transmitted pressure that compresses the fourth ventricle.\(^6\) Initial emergency treatment strategies include: elevating the head of the bed 30 degrees, osmotic diuretics such as mannitol and furosemide, short-term hyperventilation, steroids, or cerebrospinal drainage via ventriculostomy.\(^5–8\)

In conclusion, despite intracranial tumors generally being slow growing masses, this patient demonstrates how quickly one can decompensate, and how important it is to recognize these clinical signs and symptoms of an intracranial lesion. Although these symptoms (i.e. Cushing response) are extremely rare, the ED physician should be aware and appreciate their clinical significance.
